$\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ (LSMO) thin films (with a thickness of 10, 20, 60, 75, and 100 nm) were grown on SrTiO_3 (STO)-buffered silicon (001) substrates by reactive molecular-beam epitaxy. X-ray diffraction (XRD) revealed the heterostructures to be fully epitaxial with orientation relationship (001) LSMO || (001) STO || (001) Si and [100] LSMO || [100] STO || [110] Si. Root mean square roughness was about 0.5 nm as measured by atomic force microscopy (AFM) for films of 10–75 nm thicknesses, and about 1 nm for the 100 nm thick LSMO film.

Normalized Hooge parameters in the $(0.95 \pm 0.25) \times 10^{-30}$ – $(3.41 \pm 0.71) \times 10^{-30} \text{ m}^3$ range were measured at 300 K, which are comparable to the noise level typically measured in the best LSMO films on (001) STO substrates. Overall these very low noise LSMO films with thicknesses in the 10–100 nm range grown on STO/Si showed properties rivaling those of LSMO films deposited on (001) STO single crystal substrates, thus demonstrating their potential use for LSMO-based devices on silicon substrates.

1 Introduction Oxide perovskites are in demand for industrial applications as a result of their diverse physical properties [1, 2]. In particular the colossal magnetoresistance observed in manganite compounds has been actively studied in view of its possible applications to innovative magnetic devices [3, 4]. It is desirable to grow epitaxial oxide thin films on silicon in order to integrate them with Si-based devices [5]. Such integration involves several challenges including the removal of the amorphous SiO_2 layer naturally present at the silicon surface, the large difference in thermal expansion coefficient between Si and oxides, and structural compatibility.

During the past years, many materials have been considered as buffer layer for growing epitaxial $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ (LSMO) thin films on silicon [6–11]. Polycrystalline LSMO films with a metal-to-insulator transition temperature T_{MI} of 225 K are generally obtained

if grown on silicon covered by the native amorphous SiO_x layer [6]. Among possible buffer layer materials, SrTiO_3 perovskite with a cubic unit cell of 0.3905 nm is widely used for the epitaxial integration of functional oxides on silicon. Significant progress has been made in the recent years. The work of McKee et al. [12] demonstrated the growth of high quality epitaxial STO films on Si (001) substrates by molecular-beam epitaxy, paving the way to many other related work involving the epitaxial growth of STO on silicon [13–19]. Polycrystalline LSMO films grown on STO/Si by pulsed laser deposition (PLD) [20] or by sputtering [21] have been reported. Textured and oriented LSMO/STO/Si films were grown by PLD on STO buffered-Si with the STO layer showing both (110) and (001) orientations [22]. Moreover, Pradhan et al. [10] reported ferromagnetic temperature transitions T_C of 320 and 180 K for 55 and 20 nm LSMO thick films on STO/Si, respectively. Atomic

force microscopy (AFM) data measured in $2\ \mu\text{m} \times 2\ \mu\text{m}$ images of the same 55 and 20 nm thick films showed a root mean square roughness of 2 and 1 nm, respectively.

In this paper, an STO layer followed by an LSMO layer were grown on Si (001) by reactive molecular-beam epitaxy. We investigated the structural, topological, magnetic, electrical resistive, and low-frequency noise properties of 10–100 nm thick LSMO thin films deposited on STO/Si. Section 2 describes the conditions of film preparation, their structural and surface morphology properties. Magnetization and electrical resistivity of unpatterned films versus temperature are presented in Section 3. Section 4 is devoted to electrical low-frequency noise measurements, which is well accepted as a much more sensitive indication of the quality of materials or devices than static properties such as resistivity [23]. We present some results performed at 300 K, and analyzed within the framework of the semi-empirical Hooge relation [24]. The latter routinely enables the evaluation of noise level in materials of different compositions, sizes, and in different bias conditions.

2 Sample preparation, structural, and surface morphology We grew epitaxial STO thin films on (001) Si by reactive molecular-beam epitaxy. The growth was

monitored by reflection high-energy electron diffraction (RHEED). For the 20 nm thick STO buffer layers, we used the same growth process reported previously [18, 25]. Following the growth of the STO buffer layer, LSMO thin films with different thicknesses (10–100 nm) were deposited on top using a codeposition technique in which strontium, manganese, and lanthanum were simultaneously evaporated from effusion cells in the presence of distilled ozone. The fluxes of the constituent elements were measured using a quartz crystal monitor. The LSMO film was grown at a substrate temperature of 670°C in a distilled ozone background pressure of 5×10^{-7} Torr [25]. The RHEED pattern at the completion of the 60 nm thick LSMO layer completing the LSMO/STO/Si heterostructure is shown in Fig. 1.

X-ray diffraction (XRD) and AFM in tapping mode were used to investigate the structural and morphological properties of the samples. Figure 2 shows the XRD patterns in the θ - 2θ configuration of the 10, 20, 60, 75, and 100 nm thick LSMO/STO/Si heterostructures.

Rocking curves in ω were measured for all the heterostructures. The full width at half maximum (FWHM) values around the (002) peaks of the rocking curve of STO and LSMO are reported in Table 1. They were in the 0.22° – 0.31° and 0.18° – 0.33° ranges, respectively, which are among lower reported values for epitaxial oxide films grown on silicon substrates. A pole figure of the 101 peak of the 60 nm

Figure 1 (online color at: www.pss-a.com) RHEED patterns at the end of the growth of a (60 nm)LSMO/(20 nm)STO/Si heterostructure. (a) RHEED image along the [100] azimuth of LSMO. (b) RHEED image along the [110] azimuth of LSMO.

Figure 2 XRD patterns in the θ - 2θ configuration of the (a) 10 nm thick; (b) 20 nm thick; (c) 60 nm thick; (d) 75 nm thick; (e) 100 nm thick LSMO films on STO/Si.

Table 1 Summary of the structural, surface morphological, magnetic, and electrical properties of all the 10–100 nm thick LSMO/STO/Si films.

LSMO thickness (nm)	FWHM STO(002) (°)	FWHM LSMO(002) (°)	rms roughness (nm)	ρ at 300 K ($10^{-5} \Omega \text{ m}$)	T_C (K)	$4\pi M_s$ at 294 K (kOe)	α_H/n at 300 K (10^{-30} m^3)
10	0.31	0.33	0.59	3.8	320	2.40	3.41 ± 0.71
20	0.27	0.29	0.42	2.6	330	2.85	1.62 ± 0.32
60	0.26	0.22	0.50	2.8	330	2.80	0.95 ± 0.25
75	0.22	0.18	0.57	2.4	330	2.84	1.73 ± 0.48
100	0.22	0.26	0.96	1.4	345	4.00	2.75 ± 0.58

FWHM STO(002) and FWHM LSMO(002) are the FWHM values of the (002) peaks in an ω -scan configuration for STO and LSMO, respectively; rms roughness is the root mean square roughness measured in $1 \mu\text{m} \times 1 \mu\text{m}$ AFM images; ρ at 300 K is the electrical resistivity at 300 K; T_C is the Curie temperature; $4\pi M_s$ is the saturated magnetization at 294 K; α_H/n at 300 K is the normalized Hooke parameter at 300 K.

thick LSMO/STO/Si heterostructure showed that the heterostructure was epitaxial with an orientation relationship of (001) LSMO \parallel (001) STO \parallel (001) Si and [100] LSMO \parallel [100] STO \parallel [110] Si.

Roughness was measured by AFM in tapping mode. As shown in the $1 \mu\text{m} \times 1 \mu\text{m}$ images of Fig. 3 very smooth films were obtained. The root mean square roughness measured in the $1 \mu\text{m} \times 1 \mu\text{m}$ images was about 0.5 nm for

films of 10–75 nm thicknesses, and about 1 nm for the 100 nm thick LSMO film, as reported in Table 1. Again, these values are the lowest values reported in the literature for manganites on silicon substrates [10, 26].

3 Magnetization and resistivity of unpatterned films versus temperature Magnetization was measured by a superconducting quantum interference device (SQUID)

Figure 3 (online color at: www.pss-a.com) $1 \mu\text{m} \times 1 \mu\text{m}$ AFM images in tapping mode of the (a) 10 nm thick; (b) 20 nm thick; (c) 60 nm thick; (d) 75 nm thick; (e) 100 nm thick LSMO films on STO/Si.

Figure 4 (online color at: www.pss-a.com) Temperature dependence of the saturated magnetization ($4\pi M_s$) of the 10–100 nm thick LSMO/STO/Si films at an in-plane applied magnetic field of 5 kOe.

magnetometer in the 10–400 K range. Figure 4 shows the saturated magnetization versus temperature behavior under an in-plane applied magnetic field of 5 kOe. The magnetization shows a sharp transition behavior. All curves have been fitted by a theoretical standard static Brillouin magnetization function. The Curie temperature T_C estimated by this fitting is within the range 320–345 K (see Table 1) for all films and is in good agreement with the bulk theoretical values ($T_C \approx 350$ K). Saturated magnetization values at low temperature ($T = 10$ K) lies in between 5800 and 6900 Oe for all samples, which is close to the expected bulk value of 7350 Oe. The good agreement between theoretical and experimental values is slightly decreasing for thinner films, as frequently reported [10, 28].

A remarkable point in the case of our series of samples is that all samples, even the thinnest ones, show saturation magnetization and Curie temperature values close to the theoretical ones. In the 10 nm LSMO, the magnetization value at room temperature ($T = 294$ K) is 42% of the saturated magnetization value at very low temperature ($T = 10$ K) while in the 100 nm thick film, the magnetization value at room temperature is only 60% of the saturated magnetization at low temperature. These results are again comparable to those achieved for LSMO films directly grown on single crystal STO substrates [29] and arise hopes for room temperature applications. Further static and dynamic magnetic characterizations of the 20 and 60 nm thick LSMO films on STO/Si can be found elsewhere [30].

Electrical transport measurements were performed by the standard four-probe technique as a function of temperature on unpatterned films. Figure 5 shows the electrical resistivity versus temperature curves measured on the 10–100 nm thick LSMO films. The measured electrical resistivity values were in the 1.4×10^{-5} – $3.8 \times 10^{-5} \Omega \text{ m}$ range at 300 K for all the LSMO thicknesses (see Table 1), which is very close to the bulk value [27]. All films showed a metal-insulating transition temperature T_{MI} in the 350–380 K range.

Figure 5 (online color at: www.pss-a.com) Electrical resistivity versus temperature characteristics of the 10–100 nm thick LSMO/STO/Si films.

4 Electrical low frequency noise measurements

For electrical low frequency noise measurements, a 200 nm thick gold layer was ion beam sputtered on the LSMO/STO/Si heterostructures in order to make low resistive electrical connections. The LSMO thin films were patterned by UV photolithography and argon ion etching to form 50 μm wide and 150 μm long bridges. Each structure includes two gold pads for supplying the current and two gold pads carrying out the voltage measurements in order to form four probe connections. The connections between the external circuitry and the patterned films with gold contact pads were made using a four-probe system. The electronics readout mainly consists of a low noise high output impedance DC current source [31] and a dedicated low noise instrumentation amplifier with a voltage gain of about 1000, a 1 Hz–100 kHz bandwidth, an input voltage white noise of $20 \times 10^{-18} \text{ V}^2/\text{Hz}$, and negligible input current noise. A spectrum analyzer (Agilent 89410A) calculates the noise spectral density for frequencies in the 1 Hz–100 kHz range.

Low frequency noise comes from various origins that lead to different frequency dependences. As shown in Fig. 6 for the case of the 20 nm thick LSMO/STO/Si film, we could clearly observe two types of noise in all our samples: Johnson (or thermal) noise, and $1/f$ (or flicker) noise. The first one depends neither on the bias current nor on the frequency. It is due to spontaneous fluctuations induced by thermal excitations and it is related to the electrical resistance R of the sample (the voltage noise spectral density is given by the Nyquist formula $4k_B TR$, where k_B is the Boltzmann constant and T the temperature). The second one is a frequency-dependent component in $1/f^\gamma$, showing a parameter γ close to -1 , which gives the name of “ $1/f$ ”. This $1/f$ noise is usually described by the Hooge empirical relation, which does not have any physical basis but has been shown to agree well with experimental observations for electrically homogeneous samples. This relation is given by the following

Figure 6 (online color at: www.pss-a.com) Voltage noise spectral density S_V spectra measured at 300 K on the 20 nm thick LSMO/STO/Si film patterned as a $50\ \mu\text{m}$ wide $150\ \mu\text{m}$ long bridge for different bias current I .

general formula [23]:

$$\frac{S_V}{V^2} = \frac{\alpha_H}{n} \times \frac{1}{\Omega \times f^\gamma}, \quad (1)$$

where S_V is the voltage noise spectral density (V^2/Hz), V the sample voltage (V), α_H the Hooke parameter (dimensionless), n the charge carrier density (m^{-3}), Ω the sample volume (m^3), and f is the measuring frequency (Hz). It is very useful to compare the $1/f$ noise magnitude in different materials independently of the sample volume and the bias conditions. In order to estimate the voltage noise spectral density of the material, the noise of the electronic readout and the noise of the voltage contacts were removed. As presented in Fig. 7, the quadratic dependence of S_V versus V expected from Eq. (1) was verified within experimental error bars for all samples at 300 K, thus enabling a correct estimation of α_H/n values.

As reported in Table 1, normalized Hooke parameters α_H/n in the $(0.95 \pm 0.25) \times 10^{-30}$ – $(3.41 \pm 0.71) \times 10^{-30} \text{ m}^3$

Figure 7 (online color at: www.pss-a.com) Voltage noise spectral density S_V at 1 Hz and 300 K versus voltage across the $50\ \mu\text{m}$ wide $150\ \mu\text{m}$ long bridges for all of the 10–100 nm thick LSMO/STO/Si films. Error bars and fitted curves showing the quadratic dependence of S_V versus V are added to the measured data.

range were measured at 300 K, which are comparable to the noise level typically measured in the best LSMO films on STO single crystal substrates with α_H/n values of $0.8 \times 10^{-30} \text{ m}^3$ [32–34].

5 Conclusions In summary, we grew epitaxial LSMO thin films with thicknesses ranging from 10 to 100 nm on STO buffered (001) Si substrates. The samples show very low noise. The FWHM of the LSMO 002 rocking curves were about 0.2° – 0.3° . AFM measurements confirmed that the film surfaces were smooth (RMS roughness of 0.5 nm for 10–75 nm LSMO thicknesses). The films showed electrical and magnetic properties comparable to those of LSMO grown on (001) STO single crystals. Low frequency noise measurements were performed at 300 K. Normalized Hooke parameters were measured in the $(0.95 \pm 0.25) \times 10^{-30}$ – $(3.41 \pm 0.71) \times 10^{-30} \text{ m}^3$ range, demonstrating their potential use in innovative applications based on LSMO thin films grown on silicon substrates operating at room temperature.
